## ABSTRACT

In [1], a novel structure was discussed for representing the matrices that can be built from an  $n$ -variable  $r$ -valued reversible/quantum circuit. This structure, called a QMDD, takes on a form similar to that of a reduced-ordered-binary-decision-diagram (ROBDD). It is known that the order of variables used for developing an ROBDD from a binary logic circuit is relevant to the size and structure of that ROBDD [3]. This paper determines what effect, if any, variable order has on the QMDD structure and proposes a simple heuristic for choosing a ‘good’ variable order.

## 1. INTRODUCTION

Recent developments in the field of quantum mechanics have brought to light the possibility of the future existence of quantum computers. To this end, current computer scientists are beginning the theoretical research towards the use and benefit of quantum computers. This research requires tools for representation of quantum circuits and the ability to simulate quantum computation.

The work presented in [1] is a tool for representing quantum circuits on a classical computer. The software implements a model of a quantum circuit called a Quantum Multiple-Valued Decision Diagram (or QMDD). The existing software allows for creation of the model of a circuit and some analysis on the size and time complexity of that circuit.

In this work the implementation developed in [1] was extended to include a more robust set of quantum gates. Section 2 contains some background material on quantum circuits. A discussion of the existing implementation and the extension completed is included in Section 2. After completing the extension, an analysis of the effect of variable order on the QMDD structure was completed; this is discussed in Section 3. Following that, the paper discusses some results and future work in sections 4 and 5 respectively.

## 2. BACKGROUND

### 2.1. Quantum Circuits

Quantum circuits are similar to traditional logic circuits in that they are made up of wires and gates. However, quantum circuits are arranged in a much different fashion than traditional logic circuits. Figure 2.1 below shows an example of a traditional logic circuit (a) and an example of a quantum circuit (b). Quantum circuits can be developed to represent traditional logic functions (both binary and multi-valued functions). They are also capable of computing multiple traditional logic functions with one circuit.

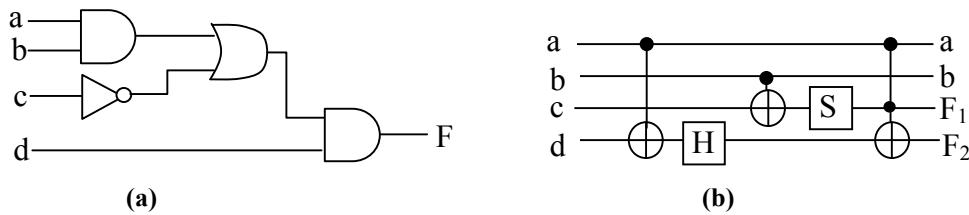

Figure 2.1

Each line in a quantum circuit represents a quantum bit, or qubit. Qubits are actual physical quantum mechanical objects that physicists are attempting to manipulate and control. Most of the discussion in this paper will be around using qubits as a mathematical representation of the physical objects.

Similar to traditional bits, qubits exist in states; traditional bits hold the states 0 or 1, whereas qubits can hold the states  $|0\rangle$  and  $|1\rangle$  (This notation is standard across the field of quantum mechanics). The difference with qubits is that they are able to exist in states other than  $|0\rangle$  and  $|1\rangle$ , and with qubits you can form linear combinations of states called superpositions (Figure 2.2). Both  $\alpha$  and  $\beta$  are complex numbers. [2]

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$$

**Figure 2.2**

Qubits are probabilistic objects as we cannot measure the actual state of a quantum bit. When a qubit is measured the value obtained is either a 0 or 1. When a measurement takes place the value of the qubit will be a 0 with probability  $|\alpha|^2$  or a 1 with probability  $|\beta|^2$ , and since probabilities sum to one  $|\alpha|^2 + |\beta|^2 = 1$ . The states  $|0\rangle$  and  $|1\rangle$  form an orthonormal basis for a vector space which includes all vectors of the form  $[\alpha \beta]$ .

Each gate in a quantum circuit is a combination of a target and zero or more controls. The target is placed on the qubit line it needs to effect and the controls, if any, are placed on other qubit lines. A quantum gate with no controls is a single-qubit gate; single-qubit gates always affect the qubit line they are on (called target lines). Quantum gates with controls only affect the target line if all lines with controls (called control lines) are on (hold a value of 1). The word line and variable will be used interchangeably throughout this paper as variables are used to represent qubits in mathematical notation.

## 2.2. Matrix Representation

The application of a quantum gate to a qubit results in a transformation of the qubit. As these transformations are linear they can be represented as a linear combination of the  $|0\rangle$  and  $|1\rangle$  states. All single-qubit quantum gates can be represented as a two by two matrix that causes a linear transformation on the vector  $[\alpha \beta]$ . Quantum gates with controls are represented by a  $2^b \times 2^b$  matrix where b is the sum of targets and controls for that gate. Each control line is represented by placing a two by two identity matrix on the diagonal in the  $2^b \times 2^b$  matrix and the target is represented by its single-qubit matrix. (Figure 2.3)

$$\begin{matrix} \text{---} & \boxed{S} & \text{---} \\ \begin{bmatrix} 1 & 0 \\ 0 & i \end{bmatrix} \end{matrix}$$

$$\begin{matrix} \begin{array}{c} \bullet \\ \text{---} \\ \boxed{S} \\ \text{---} \end{array} & \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & i \end{bmatrix} \end{matrix}$$

**Figure 2.3**

The one property that all of these matrices hold in common is they are unitary. For any matrix G that represents a quantum gate, it is unitary if  $\mathbf{G}'\mathbf{G} = \mathbf{I}$  where  $\mathbf{I}$  is the identity matrix and  $\mathbf{G}'$  is the adjoint of  $\mathbf{G}$ . This is in fact the only constraint on what matrices represent quantum gates; and, since there are “infinitely many two by two unitary matrices, [there exists] infinitely many single-qubit gates” [2 p.19].

The matrix for a quantum gate in a circuit actually takes into consideration all lines of the circuit (the target line, the control lines and all non-control lines). To form a final transformation matrix which represents the entire quantum circuit, the individual gate matrices are multiplied together in the order that the gates are written in the circuit. The matrix for a quantum circuit is  $2^n \times 2^n$  where n is the number of lines in the circuit.

## 2.3. QMDD Representation

The QMDD representation is described fully in [1]. The following is a brief overview of the work presented in that paper. Three vital functions are defined in the QMDD implementation: QMDD addition, QMDD multiplication and QMDD Kronecker product [4]. These three functions are defined based on the definitions of the corresponding matrix operations. These three functions are key to constructing a QMDD from a circuit definition.

The circuit to be represented is defined in a text file as follows: The first line of the file defines the number and label of each line (qubit) in the circuit. This line is followed by a ‘begin’ line. The next n lines define each of the n gates in the circuit. The gate type is listed first followed by a space and then a comma separated list of control lines. The last item in this comma separated list is the target line. The circuit definition is ended by the ‘end’ line.

The software reads in the circuit implementation one gate at a time. It proceeds to build the QMDD that would represent the gate if it was alone in the circuit. After building the individual gate it multiplies it by the existing QMDD definition using the multiplication function. This becomes the current QMDD definition. This process repeats until the entire file has been traversed.

In [1] the authors had implemented this tool to represent circuits containing only NOT, controlled-NOT, controlled-V and controlled-V<sup>+</sup> gates. As part of the work for this paper the Hadamard, Pauli-Y, Pauli-Z, Phase and  $\pi/8$ -Rotation gates were added to the implementation.

The authors also implemented some statistics tracking tools for testing the efficiency of their implementation. As described in [1], the authors took several measures to improve this efficiency as large circuits create large matrices and that means large amounts of space and time for manipulating them. Due to the creation of a separate QMDD for each gate and its subsequent manipulation into the larger QMDD, the authors felt it necessary to track how many nodes were created throughout the process. Also, they report the number of nodes in the final QMDD.

The authors felt they could save time by implementing a table to hold already computed values, as many computations are repeated in the creation of a QMDD. They track the number of times this table was accessed and how many times a ‘hit’ occurs (a ‘hit’ occurs when the value to be computed is in the table) for each type of calculation (addition, multiplication and Kronecker products).

The authors also implemented a timing tracker that read the clock time before and after the process ran. This was changed for this paper to read the processor’s clock tick counter instead. This gives a more accurate value for how long the process takes. The implementation uses the rdtsc assembly instruction for x86 based architecture processors. This instruction is executed twice: once before the application runs and once after. The value in the TIME columns is determined by subtracting the first value from the second.

### 3. VARIABLE REORDERING

The main goal of this research was to determine if the order of the lines in the quantum circuit mattered to the construction of the QMDD. When beginning this research the hypothesis I held originally was that this order would not matter as one can rearrange the lines in a quantum circuit and it does not affect the outcome of the circuit. That hypothesis, as was soon discovered, was incorrect.

Several circuits were defined and the QMDD’s were constructed for every possible variable order. The statistics gathering tools in the implementation allowed tracking of the following values: final node count (FNC), total node count (TNC), compute table accesses (CTA), percent of addition hits/addition accesses (ADD), percent of multiplication hits/multiplication accesses (MULT), percent of Kronecker hits/Kronecker accesses (KRON), and clock ticks elapsed (TIME).

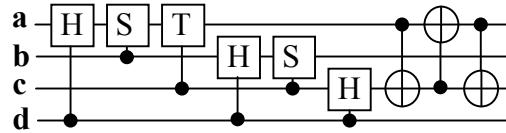

Statistics were obtained for each circuit three times. The only statistic that changes is the TIME. This statistic was recorded three times and averaged; the average value is tracked in the AVG column. As the TIME statistic is affected by how busy the processor is, outliers occurred in this data. An outlier is any data point that is greater than ten percent above or below the average. When an outlier was found the statistics for that order alone were obtained again.

The first circuit analyzed was a 3-bit Fourier Transform circuit. This is the only circuit in the group which has a defined functionality. The remaining circuits were built to test specific properties. A general discussion will follow each circuit diagram explaining the trends noticed. Then in section 4 there will be a discussion of the conclusions drawn from these trends.

All statistics attained from these tests are attached in appendix A. These statistics will be referenced frequently throughout this section of the paper. The main tables in appendix A are all sorted by the AVG statistic in ascending order as this appears to be the measurement most affected by the variable order. Other sub-tables are provided as well that are sorted differently. An explanation of the sort is described when the table is referenced in the paper.

A few definitions relating to the discussions of the circuits will now be explained. The **variable order** is a listing of the circuit line names (i.e. abcd is a variable order for a four line circuit). Two lines are **neighbors** if they are side-by-side in the variable order. A line being **early order** means the line name is listed before the midpoint of the order; conversely, being **late order** means it is listed after the midpoint of the order. The **upper region** of the data is the top values in the table when the data is sorted (when sorted by AVG this means those orders with the shortest average run times); conversely, the **lower region** is the bottom values in the table when the data is sorted. A gate that has a control on one line and a target on another line is considered **shared** by those two lines (every gate with at least one control is a **shared gate**). The **distance** between two gates is determined by the number of gates between them in the circuit.

### 3.1. Circuit 1

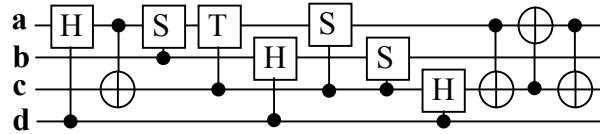

The data for circuit 1 is in table A.1.1. A noticeable trend that shows in the upper region of the data is that line **b** appears consistently early order. Another significant trend is that lines **a** and **c** are frequently neighbors in this region of data; however, lines **a** and **c** appear to be separated from each other in the lower region.

*Conjecture:* those lines with the greatest number of shared gates being neighbors in the variable order decrease the average running time.

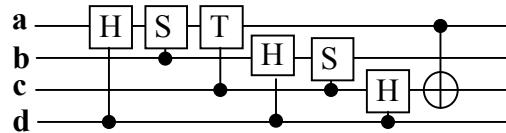

As lines **a** and **c** contain the most shared gates we would expect them to be neighbors in the upper region. To test this, statistics were run on a circuit containing more gates shared by lines **a** and **c**, as well as a circuit with less of these gates.

#### 3.1.1. Circuit 1A

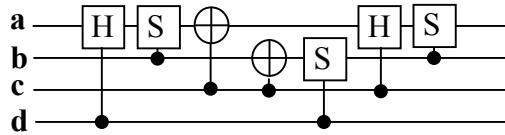

The data for this circuit is in table A.1.2. There does not appear to be any significant change in the data. The expected result here was that there would be a tighter coupling between lines **a** and **c** in the upper region. Not seeing a significant change may be due to lines **a** and **c** being as tightly coupled as possible in the first version of this circuit. As all orders with line **b** early order are at the top there cannot be any real change in the upper region.

#### 3.1.2. Circuit 1B

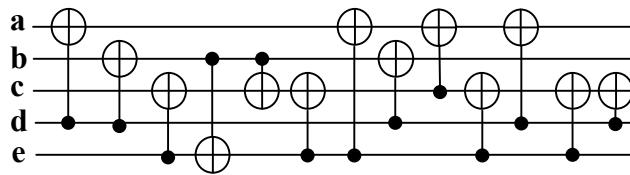

The data for this circuit is in table A.1.3. With this circuit it was expected to see less coupling between lines **a** and **c**. In the data for this circuit it is possible to see this uncoupling. In the upper region (where line **b** is consistently early order) orders with lines **a** and **c** separated appear closer to the top of the region than in circuit 1. Also, in the lower region we see orders where lines **a** and **c** are neighbors lower in this region than in circuit 1.

### 3.2. Circuit 2

The data for circuit 2 is in table A.2. The only noticeable trend in this data is that the line with the most controls on it (line **c**) is consistently early order in the last four rows of the lower region.

### 3.3. Circuit 3

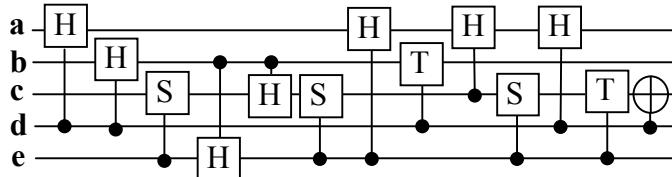

The data for circuit 3 is in table A.3.1. It was found that circuits with five qubits showed more noticeable trends as there was more data to investigate. When sorted by AVG the data showed a significant trend in the upper region: line **a** showed up most frequently early order. Line **a** is the line in the circuit with the fewest controls; it has zero.

*Conjecture:* lines with fewer controls early order cause a smaller average running time.

In the lower region for this data there is a trend towards lines **d** and **e** being early order. Lines **d** and **e** contain a significant number of the controls in this circuit.

*Conjecture:* lines with many controls, appearing early order, cause a larger average running time.

#### 3.3.1. Circuit 3A

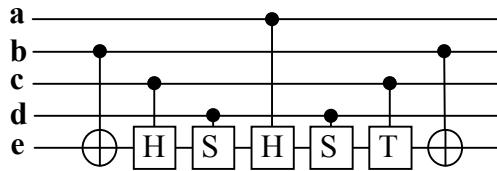

This circuit was tested to test whether the gates involved have a significant effect on the running time of the circuit. This is the exact same circuit as circuit 3, however, almost all of the CNOT gates have been changed to Hadamard, Phase and Rotation gates. To begin with, in order to run the test on this circuit the size of the table of computed values had to be increased from 256 entries to 1024 entries. Any smaller and the test would end prematurely for some orders and display an error message.

As can be seen in table A.3.2 the average running time (AVG) is much larger for this circuit. Also, the range of the AVG statistic is now about 33,000,000 whereas for circuit 3 it was about 1,400,000.

Other than this significant change, there seems to be no relevant new trend to the data. The same trends shown in circuit 3 seem to hold for this circuit.

### 3.4. Circuit 4

The data for circuit 4 is in table A.4.1. This circuit showed one significant trend in the upper region: lines **d** and **a** show up frequently early order. There also appeared to be two trends that showed in the lower region. In this region, line **b** is consistently early order and line **e** is frequently late order.

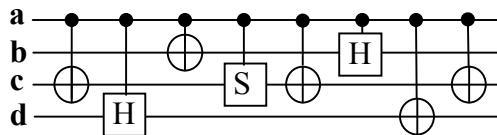

*Conjecture:* gates of greater distance that are connected to the same line will cause a longer average running time if placed early order.

Line **b** contains controls for the two gates in the circuit that are the furthest distance apart. Lines **d** and **a** are those that contain the fewest controls and contain gates that are closest together.

*Conjecture:* gates of shorter distance that are connected to the same line will cause a shorter average running time if placed early order.

Taking the data in the upper region that follow the trend mentioned above and sorting it by FNC resulted in most orders beginning with line **d** filtering to the top of the data. The data sorted in this fashion is in table A.4.2.

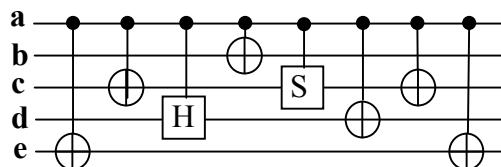

### 3.5. Circuit 5

Data for circuit 5 is in table A.5. This circuit was designed to test what effect control lines really have on the variable order. As can be seen in the data, line **a** plays a significant role. In the lower region, line **a** is consistently early order which reinforces the theory that lines with many controls appearing early order cause a larger TIME statistic. Line **a** also appears consistently late order in the upper region.

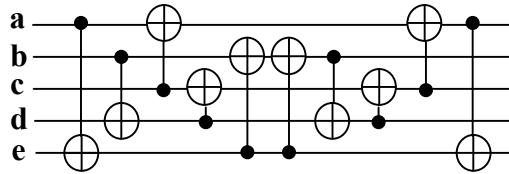

There also appears a trend in the upper region for lines **b** and **d** to be early order. The circuit shows no significant reason for this other than those lines having the least number of targets.

### 3.6. Circuit 6

Data for circuit 6 is in table A.6. This circuit shows similar trends to circuit 5. Line **a** is consistently early order in the lower region and consistently late order in the upper region. Those trends are more noticeable in this data as this circuit is five lines where as circuit 5 is four lines.

### 3.7. Circuit 7

The data for circuit 7 is in table A.7. The data in the table is sorted by AVG column. I sorted the data by each of the statistics recorded and then reviewed each sort for trends. There were no evident trends in any of the data for any of the sorts.

*Conjecture:* Circuits that have evenly distributed targets and controls on each line will be difficult to order effectively.

This circuit has evenly distributed targets and controls as there are two targets and two controls on each line. Also, with this circuit there appears to be evidence to refute the conjectures made about circuit 4 as there is no trend towards lines **a** or **e** causing a longer or shorter running time.

## 4. RESULTS

For every circuit analyzed, a significant difference was seen in the average running time between the best and worst variable order for that circuit. The worst AVG value was at least double the best AVG value in all cases. This shows that the variable order indeed has an effect on the running time of the software. Seeing as the only functionality the software performs at the moment is to build a QMDD of the circuit the aforementioned fact also shows that the variable order has an effect on the complexity of the QMDD.

The conjectures mentioned throughout this presentation can be utilized to develop an initial heuristic for determining a ‘good’ variable order given the circuit definition. I would begin by applying the conjectures from circuit 3 and then attempting to use the conjectures from circuit 1 to pair lines up. Seeing as these are only conjectures, they have yet to be fully tested. That is why I would be unsure how to handle the conflict seen about gate distance.

## 5. FUTURE WORK

This work is just a preliminary analysis as one would need a more complex and rigorous suite of test circuits to fully evaluate the QMDD structure. As far as I could tell there is no standard set of circuits that exist to test a representation structure this rigorously; some future work exists in finding one.

With a more rigorous analysis I am sure there are more trends that would be found. Also, the conjectures developed in this work need to be fully tested.

After finding more trends and fully testing the conjectures presented here, I am confident a sound heuristic could be developed to determine a ‘good’ variable order for the QMDD structure.
